

## ANEXOS

## Anexo A

Para modelar las pensiones y la prima de un seguro de vida se necesitan ciertas medidas biométricas e hipótesis como:

### Hipótesis

Demográficas: Experiencia Mexicana 2000-1.

Financieras: Tasa real de descuento (tasa de interés) 5.75%, 3% y 2%.

Tasa real de incremento a la pensión: 1%, 0%.

Tasa real de incremento al salario mínimo: 3%, 2% y 1%.

### Notación biométrica

|                           |                                                                                                           |
|---------------------------|-----------------------------------------------------------------------------------------------------------|
| $l_x$ :                   | Número de personas vivas a edad $x$ .                                                                     |
| $p_x$ :                   | Probabilidad de que una persona de edad $x$ llegue con vida a la edad $x+1$ .                             |
| $q_x$ :                   | Probabilidad de que una persona de edad $x$ no llegue con vida a la edad $x+1$ .                          |
| $CA$ :                    | Capital asegurado.                                                                                        |
| $gi$ :                    | Gastos de adquisición.                                                                                    |
| $ge$ :                    | Gastos externos.                                                                                          |
| $i$ :                     | Tasa de interés.                                                                                          |
| $v = \frac{1}{(1+i)^t}$ : | Factor de actualización financiera, que sirve para actualizar cualquier capital futuro al momento actual. |
| $t$ :                     | Número de años a actualizar.                                                                              |
| $PP$ :                    | Prima pura.                                                                                               |
| $P''$ :                   | Prima comercial.                                                                                          |
| $\Pi$ :                   | Prima única.                                                                                              |
| $\Pi''$ :                 | Prima única comercial.                                                                                    |

La fórmula para el cálculo de la prima de un seguro de vida temporal anual renovable es:  $PP = q_x v^{1/2} CA$

$$= \frac{l_x - l_{x+1}}{l_x} v^{1/2} CA$$

El factor de actualización financiera se eleva a un medio porque se establece el supuesto de que el fallecimiento ocurre a la mitad del año.

La prima pura comercial vendría calculada como:

$$PP'' = \frac{PP}{1 - gi - ge}$$

Para calcular la prima única hay que considerar el total de años que se tome en la tabla de vida de la experiencia mexicana 2000-1 (100 años) para el caso de un seguro de vida entera, pero si se tiene un plan temporal, entonces la suma corre sobre el número de períodos considerados.

$$\Pi = \sum_{i=1}^{100} \frac{l_x - l_{x+1}}{l_x} v^{1/2} CA$$

La prima única comercial tendría como fórmula:

$$\Pi'' = \frac{\Pi}{1 - gi - ge}$$

## *Método de financiamiento de planes de pensiones*

Los métodos de financiamiento tienen como objetivos distribuir los costos del plan a través del tiempo. Para que se pueda lograr es necesario llegar a construir a la edad de retiro del contratante el capital forzoso y suficiente para pagar las pensiones además de que se debió seguir patrones de ahorro fijados con anterioridad.

Para los planes de pensiones se hace necesario diseñarlos, lo mismo se debe realizar en el sentido de las micropensiones, por lo que se debe considerar elementos como:

El **monto de la obligación total del plan**, conocido como valuación actuarial.

El **tipo de beneficio**, usualmente se utiliza el beneficio definido, en los cuales se establece de antemano el monto de los mismos que se desean otorgar. Existen tres fórmulas para calcular este beneficio:

**Beneficio cerrado.** La cantidad que se destina para crear el fondo de retiro es constante e independiente del sueldo del participante. Sea  $P(s)$  la pensión, su fórmula de cálculo es expresada por:  $P(s) = \kappa$ .

**Porcentaje nivelado.** La pensión es definida como un porcentaje del sueldo que se utilizará como base para otorgar la pensión. La fórmula es:  $P(s) = \alpha S_p$ ; donde  $S_p$  es el sueldo pensionable y  $\alpha$  el porcentaje de beneficio.

**Crédito unitario.** La pensión es calculada como un porcentaje del salario pensionable por cada año de servicio prestado en la empresa. Su fórmula es:

$$P(s) = \gamma n S_p; \text{ con } S_p = \frac{\sum_{i=0}^m S_i}{m}, \text{ } \alpha \text{ el porcentaje definido por período de}$$

servicios,  $n$  el número de períodos reconocidos,  $S_p$  es el sueldo pensionable y  $S_i$  el sueldo del participante en el  $i$ -ésimo período anterior a la fecha de retiro, donde  $m \leq n$ .

Usualmente los planes de pensiones pueden manejar más de un tipo de beneficio definido y llegar a combinar los tres tipos.

El **costo normal**, es la porción de valor presente actuarial que se asigna a un año de valuación para financiar las obligaciones del plan.

El **pasivo actuarial acumulado**, es la porción del valor presente actuarial que no se cubre con los costos normales.

El **método de financiamiento**, describe el comportamiento del fondo del plan. Hay nueve formas que son (Aguilar, 2010):

- a) **Método de pago inmediato.** Consiste en pagar únicamente las pensiones que corresponden a un ejercicio determinado. Así las contribuciones se pagan precisamente en el momento en que se sufragan los beneficios provenientes del plan y son exactamente iguales al beneficio que se otorga;
- b) **Método de reserva terminal.** Se paga íntegramente el valor presente actuarial en el momento de ocurrir el retiro. O sea, la aportación de la

empresa para cada jubilado es equivalente al valor presente actuarial de la pensión asignada a la persona que se retire;

- c) **Método de edad de entrada.** El beneficio que tiene derecho un participante se financia desde el momento que ingresa al grupo, mediante una serie de pagos periódicos iguales, así el valor presente actuarial de los beneficios a la edad de ingreso al plan se amortiza mediante aportaciones niveladas que se inician desde la fecha de ingreso al plan y finalizan en la fecha de retiro;
  - d) **Método de costeo colectivo.** Se basa en el supuesto de que la relación existente entre el valor presente actuarial de los beneficios, que son financiados mediante el crédito unitario, y el valor presente actuarial de los sueldos futuros permanece constante. De esta manera el costo normal se obtiene multiplicando la nómina del personal elegible por el cociente que resulta de dividir el valor presente actuarial de los beneficios, entre el valor presente de los sueldos futuros;
  - e) **Método de edad alcanzada.** Es el mismo que el método de edad de entrada, salvo que el pasivo inicial es calculado mediante el método de crédito unitario;
  - f) **Método individual agregado.** El costo normal total es la suma de los costos normales individuales y considera un fondo para pensión;
  - g) **Método crédito unitario.** Consiste en dividir la pensión prevista a la fecha de retiro en tantas unidades como años de servicio tenga el participante desde su fecha de ingreso al grupo hasta la fecha de retiro, pagando cada año el costo total de unidad devengada. Así la pensión anual de una unidad monetaria se divide entre  $z - y$ , donde  $y$  representa la edad de entrada y  $z$  la de retiro, y el resultado compone las unidades cuyo valor presente deberá ser íntegramente pagado;
  - h) **Método de crédito unitario proyectado.** El salario corriente es proyectado a la fecha de retiro usando una escala salarial y el beneficio de retiro es distribuido uniformemente sobre la carrera del participante del plan si la unidad de beneficio es la misma para cada año de servicio, y
  - i) **Boletín D-3.** Este boletín establece un método de financiamiento que consiste en amortizar las obligaciones durante un período equivalente a la esperanza de vida laboral del grupo de personas, amortizando las variaciones que se producen por los supuestos, así como el costo de las obligaciones adquiridas.

A continuación se describe brevemente las fórmulas correspondientes al método de edad de entrada que sería uno de los más apropiados para el caso de las micropensiones el otro modelo sería el Boletín D-3.

$x$  = edad de la persona

$r$  = edad de retiro = 65 años

*Valor presente actuarial* es el valor de las obligaciones futuras que el plan de pensiones tiene con el participante, están calculadas a la fecha de valuación. En este método es una anualidad.

Valor presente actuarial = VPA = anualidad diferida durante  $r - x$  años, con

$$a \leq x < r$$

$$VPA = {}_{r-x}|\ddot{a}_x$$

$${}_{r-x}|\ddot{a}_x = \sum_{k=r-x}^{\infty} \left( \ddot{a}_{\overline{k+1}} - \ddot{a}_{\overline{r-x}} \right)_k | q_x$$

$$\ddot{a}_{\overline{n}} = \frac{1-v^n}{1-v}$$

$${}_k| q_x = \frac{d_{x+t}}{l_x} = \frac{l_{x+t} - l_{x+t+1}}{l_x}$$

*Costo normal* es el monto de la contribución periódica del participante, éste puede ser mensual, trimestral, etc. como se haya convenido en el contrato correspondiente.

Costo normal ( $CN$ ) es el valor presente actuarial del beneficio a la edad  $a$  de entrada al plan, dividido entre una anualidad contingente a la edad  $a$  durante un período  $r - a$  años.

$$CN = \frac{{}_{r-a}|\ddot{a}_a}{\ddot{a}_{\overline{a:r-a}}}$$

$${}_{r-a}|\ddot{a}_a = CN \ddot{a}_{\overline{a:r-a}}$$

$$\ddot{a}_{\overline{a:r-a}} = \sum_{k=0}^{r-a-1} v_x^k p_a = \frac{N_a - N_{r-1}}{D_a}$$

$$D_x = l_x v^x$$

$$N_x = \sum_{t=0}^{w-x-1} D_{x+t}$$

*Pasivo actuarial acumulado (PAA).* Dada la existencia del período  $x-a$  años, durante el cual no se pagó el costo normal, se generó un pasivo actuarial acumulado que es la diferencia entre el valor presente actuarial y los costos normales futuros.

$$PAA = \begin{cases} r-x \left| \ddot{a}_x - \frac{r-a}{\ddot{a}_{a:r-a}} \ddot{a}_{x:r-x} \right|; & \text{si } a \leq x < r \\ \ddot{a}_x; & \text{si } r \leq x \leq w \end{cases}$$

*Pasivo actuarial acumulado total del fondo (PAATF).*

$$PAATF = \sum_{x=a}^{r-1} r-x \left| \ddot{a}_x l_x + \sum_{x=r}^w \ddot{a}_x l_x - \frac{r-a}{\ddot{a}_{a:r-a}} \ddot{a}_{x:r-x} l_x \right|$$

Cuando el *PAATF* ha sido totalmente financiado, el valor actuarial de los activos *F* es:

$$F = \sum_{x=r}^w \ddot{a}_x l_x - \sum \left( r-x \left| \ddot{a}_x l_x - \frac{r-a}{\ddot{a}_{a:r-a}} \ddot{a}_{x:r-x} \right| \right)$$

*Costo Total Normal (CT)* permanece constante por la conformación estacionaria de la población.

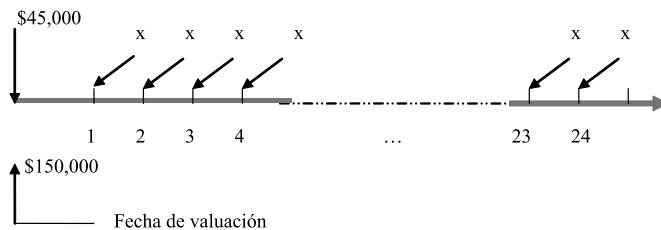

$$CT = \frac{r-a}{\ddot{a}_{a:r-a}} \sum_{x=a}^{r-1} l_x$$

El valor presente actuarial es una anualidad, por lo que a continuación se presenta una breve explicación del concepto y de lo que significa traer a valor presente la renta.

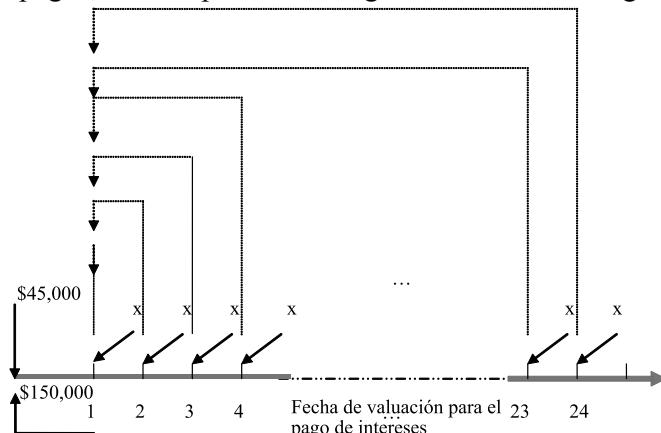

Las anualidades representan una aplicación de las matemáticas financieras, principalmente en las operaciones de crédito tanto comerciales como financieras, donde se pactan una serie de pagos periódicos que habrán de

realizarse durante su vigencia. En el caso concreto del modelo actuarial este concepto se conserva pero se incluye la probabilidad de sobrevivir a un plazo determinado.

Una operación mercantil común es aquella en la que se hacen  $n$  pagos o abonos al final de cada uno de los  $n$  períodos a los que se haya pactado la operación, este concepto muestra una forma vencida, puede también pactarse de manera anticipada, o sea al principio del período. Para exemplificar esto la figura indica el proceso que se hace con los pagos con una situación ficticia de un crédito sobre la compra de un automóvil, por el cual se va a pagar un cierto enganche y el saldo se pagará en, por ejemplo, 24 mensualidades iguales al inicio de cada mes, empezando al inicio del mes entrante después de pagar el enganche. Supóngase que el automóvil tiene un precio de \$150,000 y que se paga un enganche de \$45,000 (representa el 30% de ese precio), además se cobrará una tasa de interés efectiva mensual del 2% sobre lo que falta pagar.

Lo importante es que el diseño se hace en el momento actual por lo que la proyección debe traerse a tiempo presente, a esto se le conoce traer a valor presente los pagos, así la representación gráfica mostrará lo siguiente:

### Tabla de mortalidad edad 25 y radix 5000

$\dot{e}_x$  = Vida media completa, es una medida de la esperanza de vida de las personas que tienen edad alcanzada  $x$ , considerando que se mueren uniformemente en el año.

$e_x$  = Vida media abreviada, es una medida de la esperanza de vida de las personas que tienen edad alcanzada  $x$ , suponiendo que las personas fallecen al inicio de su aniversario.

$\mu_x$  = tasa de mortalidad.

**Prima única comercial considerando  $gi = 2\%$  y  $ge = 1\%$ .  
 Para edad de inicio 25 y radix 5000**

## *Anexo C*

## Estimación de la pensión por decrementos múltiples.

$_k q_{x+h}^j$  = tasa de decremento múltiple

Las probabilidades de decremento múltiple significan la probabilidad de que una persona salga del grupo en los próximos  $k$  años a consecuencia de la causa  $j$  y estando sujeto a todas las causas.

*x* = Edad inicial de la persona

*k* = Años trascurridos

*j* = Causa de salida (muerte o invalidez: m, i)

$_k q_{x+h}^{'} =$  Probabilidad neta de decremento

Las probabilidades netas de decremento se refieren a la probabilidad de que un participante del grupo de edad  $x+h$  tiene de abandonar el grupo en los próximos  $k$  años a consecuencia de la causa  $j$  y estando sujeto a esa causa  $j$ .

$_t p_x^{(T)} =$  Probabilidad conjunta de sobrevivencia de todas las causas ( $T$ ) entre las edades  $x$  y  $x+t$ .

$${}_t P_x^{(T)} = \left(1 - {}_t q_x'^m\right) \left(1 - {}_t q_x'^i\right)$$

*t* = Años transcurridos

## Costo normal con decrementos múltiples para el plan de pensiones por edad de entrada de 25 años, radix de 5000 (costo por 2 SMGDF como beneficio y pagadero mensualmente)

## Anexo F

## Modelo Autorregresivo

Un modelo autorregresivo de orden uno, denotado por AR(1) se representa como:  $\tilde{Z}_t - \phi\tilde{Z}_{t-1} = a_t$ , donde la serie discreta se toma en los momentos  $\tau_1, \tau_2, \dots, \tau_N$  y el proceso estocástico se denota con  $\{Z(\tau_1), Z(\tau_2), \dots, Z(\tau_N)\}$  y  $\{a_t\}$  un proceso de ruido blanco con media cero y varianza  $\sigma_a^2$ . Para que la serie sea estacionaria se requiere que la raíz de la ecuación  $1 - \phi x = 0$  se encuentre fuera del círculo unitario, por lo que se requiere que  $|\phi| < 1$  para asegurar la estacionariedad (una forma de resumir lo que la Ley de los Grandes Números y el Teorema del Límite Central hacen) del proceso AR(1).

En la siguiente tabla se muestra la estimación de los parámetros del modelo, los intervalos de confianza al 95% como el nivel de significancia de los estimadores de los parámetros.

|           | Parámetros | p        | Límite inferior del intervalo de confianza | Límite superior del intervalo de confianza |
|-----------|------------|----------|--------------------------------------------|--------------------------------------------|
| Constante | 8.007100   | 0.000000 | 5.898925                                   | 10.11527                                   |
| p(1)      | 0.982972   | 0.000000 | 0.897711                                   | 1.06823                                    |

Se estimaron con el modelo 15 pronósticos los cuales son presentados en la tabla que a continuación sigue.

|    | Pronóstico | Límite inferior del intervalo de confianza | Límite superior del intervalo de confianza | Error estándar |
|----|------------|--------------------------------------------|--------------------------------------------|----------------|
